

## 4. Regression and Causality

- Recall: Regressions give us an approximation to Conditional Expectations
- Conditional Expectations *predict* the outcome of a variable on the basis of other variables
- If we know  $E[Y|X]$  we can tell the following:
  - If you tell me a value of  $X$  (say  $x$ ), what is the average value of  $Y$  we can expect when  $X = x$ ?
  - *“Which job satisfaction can we expect in firms with performance pay as opposed to firms without?”*
- While this is a powerful property, it does not necessarily tell you:
  - If you change the value of  $X$  (say from  $x_1$  to  $x_2$ ) for objects in the population how is their average value of  $Y$  affected by this?
  - *“When we introduce performance pay, how would this change job satisfaction, on average?”*
- Typical reason: there are other variables affecting both  $X$  and  $Y$

## Counterfactuals and Causality

- The question whether a regression is causal boils down to the question whether the conditional expectation is causal
- If the CEF is causal we can estimate causal effects with a regression analysis
- To answer this question it is very useful to think about *potential outcomes* or *counterfactuals*  
*“What would have happened, when a different decision had been made?”*
- This seems hard to answer!  
(But it is often still a useful thought experiment in real life)
- But we sometimes can say something about the counterfactual using data
- When this is the case empirical research becomes very powerful!

## 4.1 Thinking about Potential Outcomes

- Suppose we want to investigate whether
  - a certain management practice  
(performance pay, wage increase, training,...)
  - causally affects some outcome variable  $Y_i$   
(job satisfaction, performance,...)
- Let  $C_i \in \{0,1\}$  be a dummy variable indicating whether the practice is implemented for person  $i$
- What we would like to know is: what is the value of  $Y_i$ 
  - if  $C_i = 1$  (“person  $i$  is treated”)
  - if  $C_i = 0$  (“person  $i$  is not treated”)
- Let this *potential outcome* be

$$Y_{C_i i} = \begin{cases} Y_{1i} & \text{if } C_i = 1 \\ Y_{0i} & \text{if } C_i = 0 \end{cases}$$

- The *causal effect* of  $C_i$  on  $Y_i$  is now  $Y_{1i} - Y_{0i}$

## The problem is:

- when we implement the practice we only observe  $Y_{1i}$
- when we do not implement the practice we only observe  $Y_{0i}$

## In real life we do not observe the *counterfactual*

- What would have happened if we had decided differently?
- The *observed outcome* is  $Y_i$  where

$$Y_i = Y_{0i} + (Y_{1i} - Y_{0i}) \cdot C_i$$

- Running a simple regression (or comparing means) in a sample yields
  - $E[Y_i|C_i = 1]$  and
  - $E[Y_i|C_i = 0]$
- Here, one may be tempted to interpret

$$E[Y_i|C_i = 1] - E[Y_i|C_i = 0]$$

as the causal effect of  $C$  on  $Y$

But note that

$$\begin{aligned} & E[Y_i|C_i = 1] - E[Y_i|C_i = 0] \\ &= E[Y_{1i}|C_i = 1] - E[Y_{0i}|C_i = 0] \\ &= E[Y_{1i}|C_i = 1] - E[Y_{0i}|C_i = 1] + E[Y_{0i}|C_i = 1] - E[Y_{0i}|C_i = 0] \\ &= E[Y_{1i} - Y_{0i}|C_i = 1] + E[Y_{0i}|C_i = 1] - E[Y_{0i}|C_i = 0] \end{aligned}$$

- The causal effect of  $C$  on the group that is treated ( $C = 1$ ) is

$$E[Y_{1i} - Y_{0i}|C_i = 1]$$

- It is called the *average treatment effect on the treated (ATT)*
  - Very often this is what we want to know
  - “*Has job satisfaction increased in a group of employees because this group now receives performance pay?*”
- But: the regression coefficient may not estimate the ATT
    - It includes  $E[Y_{0i}|C_i = 1] - E[Y_{0i}|C_i = 0]$
    - This is the *selection bias*

**We can thus decompose:**

$$\underbrace{E[Y_i|C_i = 1] - E[Y_i|C_i = 0]}_{\text{Observed difference in outcome}} \\ = \underbrace{E[Y_{1i} - Y_{0i}|C_i = 1]}_{\substack{\text{Average treatment effect} \\ \text{on the treated}}} + \underbrace{E[Y_{0i}|C_i = 1] - E[Y_{0i}|C_i = 0]}_{\text{Selection bias}}$$

- If  $E[Y_{0i}|C_i = 1]$  differs from  $E[Y_{0i}|C_i = 0]$ 
  - Treated and untreated individuals differ
  - $E[Y_{0i}|C_i = 0]$  is not the counterfactual outcome for the treated
- Then the regression estimates are biased estimates of the causal effect!

**Example:** Does a university education increase earnings?

- $E[Y_{0i}|C_i = 1]$  is the wage somebody who attended a university would earn when not having attended university
- It is very likely that  $E[Y_{0i}|C_i = 1] > E[Y_{0i}|C_i = 0]$
- Hence, we would overestimate the true returns to a university education

## Your Task

## Simulated data set: Evaluation of a sales training

- Write a script that generates a fictitious data set with 10000 observations  

```
n=10000  
df=pd.DataFrame(index=range(n))
```
- Generate a normally distributed random variable *ability* with mean 100 and std. deviation 15: 

```
df['ability']=np.random.normal(100,15,n)
```
- Generate a dummy variable *training*:  

```
df['training']=(df.ability+np.random.normal(0,10,n)>=100)
```

(Hence, more able people have a higher likelihood to be trained)
- Generate a variable *sales*:  

```
df['sales']= 10000 + df.training*5000 + df.ability*100  
+ np.random.normal(0,4000,n)
```
- This is the true causal relationship: the training increases sales by 5000
- But suppose we as researchers cannot observe *ability*
- Run a regression of sales on training & interpret the results (& save the notebook as SalesSim1)

## Recall:

- A regression estimates the Conditional Expectation Function
- The CEF gives us  $E[Y_i|C_i = 1] - E[Y_i|C_i = 0]$
- It identifies a causal effect only if  $E[Y_{0i}|C_i = 1] - E[Y_{0i}|C_i = 0] = 0$

This is satisfied if  $C_i$  is *independent* of  $(Y_{0i}, Y_{1i})$

- That is neither  $Y_{0i}$  nor  $Y_{1i}$  are systematically different for people with different realizations of  $C_i$
- Let the symbol  $\perp$  indicate independence
- If the condition

$$(Y_{0i}, Y_{1i}) \perp C_i$$

is satisfied we can use simple regressions (or here mean comparisons) to identify causal effects

## 4.2 Why are Experiments so Important?

- Suppose we have a *Randomized Controlled Trial* (RCT, A/B Test)
  - That is  $C_i$  is randomly (that is *exogenously*) assigned to the individuals  $i$
  - In turn,  $C_i$  is by construction independent of  $Y_{i0}$
  - Hence,  $E[Y_{0i}|C_i = 1] = E[Y_{0i}|C_i = 0]$
  - The selection bias is eliminated!
  - We obtain an unbiased estimator of the causal impact of  $C$  in the population
- In that case

$$E[Y_i|C_i = 1] - E[Y_i|C_i = 0] = E[Y_{i1} - Y_{i0}]$$

- A simple comparison between the averages of treatment and control yields an unbiased estimate of the causal effect
- The same holds for a regression on a treatment dummy

# Implementing RCTs in Firms: Typical Project Timeline

## 1. Preparation (1-3 months)

- Analysis:
  - Detailed analysis of current design of HR practice
  - Collection of outcome data (i.e. KPI, performance evaluations, survey data)
  - Prior qualitative analysis of HR practice
  - Analysis of quantitative data
  - Statistical power analysis
- Design
  - Development for redesign of HR practice
  - Treatment design for A/B test
  - Survey design
  - Communication strategy

## 2. A/B Testing (3-12 months)

- Duration of A/B test and number of treatments fixed
- A/B Test implemented
  - Random assignment of units to treatment (stratified randomization)
  - Communication strategy implemented
- Posterior employee survey

## 3. Evaluation (1-3 months)

- Data collection
  - Outcome data for treatment and control units before and during the treatment time collected
- Analysis
  - Estimate causal effect on
  - Performance outcomes
  - Employee attitudes (survey outcomes)
- Presentation & Choice
  - Present & discuss results
  - Proposal for roll-out

# RCT in Retailing I: Sales Bonus

- Project by Manthei/Sliwka/Vogelsang (Management Science, 2021)
- Evaluate impact of a bonus based on the average receipt (*revenue* per customer) in a discount retail chain
- Experiment I:  
Bonus for district managers in one region (Nov 2015-Jan 2016)
  - 25 district managers (152 stores) randomly assigned to the treatment
  - 24 district managers (148 stores) randomly assigned to the control
- Experiment II:  
Bonus for store managers in the same region (Nov 2016-Jan 2017)
  - 99 store managers treatment „Norm. bonus“
  - 95 Manager im treatment „Simple bonus“
  - 95 Manager in control group

# RCT in Retailing I: Sales Bonus

**Table 1.** Main Effects of Experiments I and II

	Experiment I—District level			Experiment II—Store level		
	(1)	(2)	(3)	(4)	(5)	(6)
	<i>Sales per Customer</i>	<i>Sales per Customer</i>	CI 90%	<i>Sales per Customer</i>	<i>Sales per Customer</i>	CI 90%

Cluster	49	49		50	50	
Within $R^2$	0.9427	0.9478		0.8473	0.8476	
Overall $R^2$	0.1043	0.1185		0.0497	0.0327	

*Notes.* The table reports results from a fixed effects regression with the sales per customer on the district/store level as the dependent variable. The regression accounts for time and store district fixed effects and adds fixed effects for district managers in column (2) and fixed effects for district and store managers in column (5). For experiment I, the regressions compare pretreatment observations (January 2015–October 2015) with the observations during the experiment (November 2015–January 2016). For experiment II, the regressions compare pretreatment observations (January 2016–October 2016) with the observations during the experiment (November 2016–January 2017). “Treatment effect” thus refers to the difference-in-difference estimator. All regressions control for possible refurbishments of a store. Observations are excluded if a store manager switched stores during the treatment period. Robust standard errors are clustered on the district level of the treatment start and displayed in parentheses. Columns (3) and (6) display 90% confidence intervals of the specification in columns (2) and (5), respectively. CI, confidence interval; FE, fixed effects.

\* $p < 0.1$ ; \*\* $p < 0.05$ ; \*\*\* $p < 0.01$ .

# RCT in Retailing I: Sales Bonus

## RCT in Retailing II: Talking about Performance

Manthei/Sliwka/Vogelsang (2020): Four treatments

	Bonus	No Bonus
Review	N=63	N=51
No Review	N=50	N=60

- April 2017 – June 2017 (3 Month)
- Performance Incentive:  
€0.05 for ever €1 *profit* above 80% of the planned value
- Monitoring/Performance Review:  
Biweekly reviews meetings with district managers

### Protocol:

- What did the store manager do?
- Which problems did occur?
- What does he/she plan to do next?

## RCT in Retailing II: Talking about Performance

	(1) FE	(2) FE	(3) Log FE	(4) Log FE

Overall $R^2$	0.7577	0.5955	0.6158	0.4316

*Note:* The table reports results from a fixed effects regression with the profits on the store level as the dependent variable. The regression accounts for time and store fixed effects and adds fixed effects for district manager and store managers in column 2&4. The regressions compare pre-treatment observations (January 2016 - March 2017) with the observations during the experiment (April 2017 – June 2017). *Treatment Effect* thus refers to the difference-in-difference estimator. All regressions control for possible refurbishments of a store and the companies planned value of profits. Observations are excluded when a store manager switched the store during the treatment period. Robust standard errors are clustered on the district level of the treatment start and displayed in parentheses. \*  $p<0.1$ , \*\*  $p<0.05$ , \*\*\*  $p<0.01$ .

# RCT: Promoting Pay Equity

- Field experiment in a multinational firm (Deversi/Alfitian/Sliwka (in progress))
- Starting point:
  - Managers have an annual budget for wage increases
  - Wages for a position tied to a salary band for that position
  - The firm wanted to reduce the variance of wages within the salary bands and promote pay equity for people on the same job
  - One issue:  
Gender pay gap

# RCT: Promoting Pay Equity

**Key interventions randomly assigned to 622 teams with 8954 employees:**

- *Guidance value*
  - Managers are nudged to provide more equitable increases
  - Managers see a „guidance value“ for the increase of each employee
  - High guidance value for employees low in range (and vice versa)
  - Also budget adapted so that supervisors with more employees low in range have more budget (and vice versa)
- *Budget*
  - Budgets adapted as in guidance value
  - But no guidance value shown
- *Guidance Range*
  - Budgets adapted as in guidance value
  - Managers see a suggested interval

## Your Task

## Simulated data set: Evaluation of a sales training II

- Open your SalesSim1 notebook, save it as SalesSim2 to generate a different simulation, and run the whole notebook
- Now suppose that there is new training program which is *randomly assigned*
- Add a cell at the end of the notebook to generate a dummy variable *training2* which takes value 1 for 5% randomly chosen individuals  
`df['training2']=np.random.binomial(1, 0.05, n)`
- **Note:** `np.random. binomial(1,0.05,n)` generates a vector of `n` binomial random variables with 1 trial each (taking value 1 with 5% probability)
- Assume that this new program also raises sales by 5000:  
`df['sales']= df.sales + df.training2*5000`
- Run a regression of sales on training and training2
- Interpret the results & save the notebook

## 4.3 Control Variables & Omitted Variable Bias

- But what if we do not have an experiment?
- In multiple regression we “control for” other covariates  $X_i$
- (When) does this help us to identify causal effects?
- We can write  $E[Y_i|X_i, C_i = 1] - E[Y_i|X_i, C_i = 0]$

$$= E[Y_{1i} - Y_{0i}|X_i, C_i = 1] + E[Y_{0i}|X_i, C_i = 1] - E[Y_{0i}|X_i, C_i = 0]$$

### The Conditional Independence Assumption (CIA)

If the *conditional independence assumption holds*, i.e.

$$Y_{ci} \perp\!\!\!\perp C_i \mid X_i \text{ for all values of } c,$$

(conditional on  $X$  the treatment  $C_i$  is independent of potential outcomes), then

$$E[Y_i|X_i, C_i = 1] - E[Y_i|X_i, C_i = 0] = E[Y_{1i} - Y_{0i}|X_i, C_i = 1],$$

i.e. the difference in conditional expectations has a causal interpretation.

## Note:

- This is a weaker property than the independence assumption  
 $(Y_{0i}, Y_{1i}) \perp\!\!\!\perp C_i$  above
- We do not need that  $C_i$  is independent from potential values
- But it needs to be independent for people who have the same values for a set of observable co-variates

## The ***Conditional Independence Assumption*** is crucial in many applications

- Useful question: is  $C_i$  as good as randomly assigned conditional on  $X_i$ ?
- Or, in other words: are the variables in  $X_i$  the only reason why  $(Y_{0i}, Y_{1i})$  are correlated with  $C_i$ ?
- This is also called the “*selection on observables*” assumption: i.e. selection into the treatment only depends on observable variables  $X_i$ ; beyond that it is random
- In that case a regression which controls for  $X_i$  (in a proper manner) has a causal interpretation

## Analogously: Continuous “treatment” variable

- Think in terms of a causal model  $Y_{si} \equiv f_i(s)$ 
  - $f_i(s)$  describes how an object  $i$  (person, firm, ...) responds to changes in some variable  $s$
  - or: determines the outcome for all *potential* realizations of  $s$
- Now let  $f_i(s) \equiv f(s, X_i)$
- Distinction between CEF  $E[Y_i | S_i, X_i]$  (or regression as its approximation) and causal model  $f(s, X_i)$ 
  - The CEF describes the mean of  $Y$  when I draw objects with the same values of  $(S_i, X_i)$  from the population (and regressions approximate these conditional expectations)
  - The causal model  $f(s, X_i)$  describes how  $Y$  changes when I change  $s$
- Regressions approximate the causal model when the CIA holds

## A Note on Terminology: *Identifying Assumptions*

- When we use *observational data* (that is data that we observe but which has not been generated by an experiment), we can never be entirely sure that our regression captures the causal effect
- But still for many questions it is hard to design an appropriate field experiment
- We can (and should) still try to say something about causality
- In order to do so, we typically state so called *identifying assumptions*
  - That is: we make clear under what conditions our empirical approach would capture a causal effect
- The conditional independence assumption is an example for such an identifying assumption

## Omitted Variable Bias

- Assume that the causal relationship between  $Y_i$  and  $C_i$  is determined by

$$Y_i = \alpha + \rho \cdot C_i + \gamma \cdot X_i + v_i$$

where  $v_i$  is uncorrelated with all regressors

- When the CIA holds, then  $\rho$  is equal to the coefficient in the linear regression of  $Y_i$  on  $C_i$  and  $X_i$
- But assume that we cannot (or do not) include  $X_i$  and estimate

$$Y_i = \tilde{\alpha} + \tilde{\rho} \cdot C_i + \eta_i$$

- The short regression yields (use the true causal relationship)

$$\begin{aligned}\tilde{\rho} &= \frac{\text{Cov}[C_i, Y_i]}{V[C_i]} = \frac{\text{Cov}[C_i, \alpha + \rho \cdot C_i + \gamma \cdot X_i + v_i]}{V[C_i]} \\ &= \rho + \frac{\text{Cov}[C_i, \gamma \cdot X_i + v_i]}{V[C_i]} \\ &= \rho + \gamma \cdot \frac{\text{Cov}[C_i, X_i]}{V[C_i]}\end{aligned}$$

- If  $\text{Cov}[C_i, X_i] \neq 0$  the coefficient is biased (“omitted variable bias”)

$$\tilde{\rho} = \rho + \gamma \cdot \frac{Cov[C_i, X_i]}{V[C_i]}$$

- But  $\frac{Cov[C_i, X_i]}{V[C_i]}$  is the coefficient in a regression

$$\underbrace{X_i}_{\text{Omitted variable}} = \delta_0 + \delta_c * \underbrace{C_i}_{\substack{\text{Included} \\ \text{"endogenous"} \\ \text{variable}}} + v_i$$

- Then

$$\tilde{\rho} = \frac{Cov[C_i, Y_i]}{V[C_i]} = \rho + \gamma \cdot \delta_c$$

**Hence:** If  $C_i$  is *endogenously* determined by  $X_i$  and we cannot observe  $X_i$

- then the regression will yield a biased estimate of the causal effect
- the size of this *omitted variable bias* is  $\gamma \cdot \delta_c$

- Open the SalesSim1 notebook
- Again regress
  - *Sales* on *training*
  - *Sales* on *training* and *ability*
- Regress *ability* on the “endogenous” variable *training*  
How do you interpret the coefficient of *training* in the last regression?  
(Note this is not causal! but think of CEF interpretation of regression)
- Compute the OVB using this coefficient
- Interpret the size of the OVB

## 4.4 Measurement Error

- The previous considerations suggest that multiple regressions come close to causal effects when there are proper control variables
- What if we can imperfectly measure variables, i.e. there is *measurement error*
- Suppose that we have a causal model  $f_i(x) = \alpha + \gamma \cdot x + v_i$
- Suppose that
  - we cannot measure the  $X_i$  precisely,
  - but measure  $\tilde{X}_i = X_i + \eta_i$  where  $\eta_i \sim N(0, \sigma_\eta^2)$
- If we run a regression

$$Y_i = \tilde{\alpha} + \tilde{\gamma} \cdot \tilde{X}_i + \varepsilon_i$$

we obtain a coefficient

$$\tilde{\gamma} = \frac{\text{Cov}[\tilde{X}_i, Y_i]}{V[\tilde{X}_i]} = \frac{\text{Cov}[X_i + \eta_i, \alpha + \gamma \cdot X_i + v_i]}{V[X_i + \eta_i]}$$

But

$$\frac{\text{Cov}[X_i + \eta_i, \alpha + \gamma \cdot X_i + v_i]}{V[X_i + \eta_i]} \\ = \gamma \cdot \frac{\sigma_x^2}{\sigma_x^2 + \sigma_\eta^2}$$

- This is strictly smaller than the true causal effect  $\gamma$  as  $\frac{\sigma_x^2}{\sigma_x^2 + \sigma_\eta^2} < 1$
- This is called the *attenuation bias*:  
If there is measurement error in a variable regressions underestimate its causal effect
- Note: If you still observe a positive and significant effect
  - you are safe to conclude that the variable measured with error has an impact
  - the true effect is even larger

## Measurement Error in a Covariate

- However, measurement error can be more problematic, if it affects an important control variable
- Consider a causal population regression (i.e. the CIA holds  $Y_{ci} \perp\!\!\!\perp C_i \mid X_i$ )

$$Y_i = \alpha + \rho \cdot C_i + \gamma \cdot X_i + v_i$$

- Assume that we are interested in the effect of  $C$
- But we measure only a “proxy”  $\tilde{X}_i = X_i + \eta_i$  for the omitted variable  $X_i$

The problem is:

- measurement error leads to a (downward) biased estimate of  $\gamma$
- we therefore do not properly condition on  $X$
- we may get a biased estimate of  $C$  as the coefficient of  $C$  captures some of the remaining influence of  $X$  on  $Y$
